

INHIBITOR INSENSITIVITY OF OXYGEN CONSUMPTION OF CELLS FROM RAJA ERINACEA  
GASTRIC MUCOSA

George W. Kidder III

Dept. of Biological Sciences, Illinois State University, Normal, IL 61761

Acid secretion by the gastric mucosa of the little skate is an aerobic process. Since this tissue contains an apparently normal cytochrome system (Kidder & Kidder, Bull. MDIBL 25:40, 1985) the elimination of cytochrome oxidase activity by inhibitors should mimic the effect of anoxia. However, acid secretion is not abolished by a high  $\text{CO}/\text{O}_2$  ratio (Kidder & Kidder, Bull. MDIBL 26:43, 1986), tissue oxygen uptake is relatively insensitive to azide (Kidder & Miller, Bull. MDIBL 27:106, 1987) and much of the cytochrome system continues to react with  $\text{O}_2$  under these conditions. An alternate cytochrome oxidase is suspected which supplies energy for gastric acid secretion. Since oxygen consumption of the chambered tissue is diffusion-limited, which requires maintaining high  $\text{O}_2$  concentrations, a cell suspension was prepared from the tissue for the present experiments.

The gastric mucosa was stripped of its heavy muscle layer, pinned mucosal side up on a parafin surface and exposed to elasmobranch Ringer's containing 1.75 mg/ml pronase (133 units/ml at  $40^\circ$ ) for 3.5 hours at  $30^\circ$  in a shaking incubator under 95%  $\text{O}_2/5\%$   $\text{CO}_2$ . The cell suspension was centrifuged, washed and resuspended in a phosphate-buffered elasmobranch Ringer's with 20 mM glucose and 10 mM beta-hydroxybutyrate. The yield was  $248 \pm 35 \times 10^6$  cells per preparation by hemocytometer ( $N=33$ ) of which  $95.6 \pm 0.5\%$  excluded eosine, in a total volume between 1 and 4 ml. Oxygen uptake was measured at  $20^\circ$  in an Instek oxygen electrode system, using 50-400  $\mu\text{l}$  of cell suspension in a 600  $\mu\text{l}$  chamber. Azide ( $\text{N}_3^-$ ) and cyanide ( $\text{CN}^-$ ) were added in volumes of 2 to 20  $\mu\text{l}$ ; oxygen uptake was determined from the slope of the recording of  $[\text{O}_2]$  vs. time, corrected for the dilution by inhibitor volume, and expressed as  $Q$  in  $\mu\text{l O}_2/10^6 \text{ cells} \cdot \text{hr}$ . The apparent  $K_m$  for  $\text{O}_2$  could be determined from the  $[\text{O}_2]$  at which  $Q$  was half of  $Q_{\text{max}}$ . Values are mean  $\pm$  SE for ( $N$ ) determinations; 9 tissues were used for each of the  $\text{N}_3^-$  and  $\text{CN}^-$  series, and 11 tissues for  $\text{CO}$  experiments.

There was considerable variability in  $Q$  between preparations. For the

Figure 1 Azide and cyanide on  $Q$

$\text{N}_3^-$  series, the uninhibited  $Q$  was  $0.704 \pm 0.034$  (67), while in the later  $\text{CN}^-$  series, the control  $Q$  was  $0.586 \pm 0.039$  (62), a statistically significant ( $P < 0.01$ ) difference. To remove variability, each inhibited value was divided by the control portion of the same run; the resulting data are shown as Figure 1. For both inhibitors, there is a small inhibition at low concentrations, but a large fraction of  $Q$  remains at high con-

centrations, as was previously observed with the isolated tissue preparation. All values are different from both 100% and zero ( $P < 0.01$ ) except that the value for  $1.67 \mu\text{M CN}^-$  ( $94.8 \pm 12.8\%$  of control) does not differ from no inhibition.

Noncompetitive inhibitors are not expected to change the  $K_m$  of an enzyme.

Figure 2 Azide and cyanide on  $K_m$

The effect of  $\text{N}_3^-$  and  $\text{CN}^-$  on the apparent  $K_m$  for oxygen is shown in Figure 2. While  $\text{N}_3^-$  has no significant effect on  $K_m$ ,  $\text{CN}^-$  markedly and significantly increases  $K_m$  at concentrations above  $10 \mu\text{M}$ . Either  $\text{CN}^-$  is competitive or a second oxidase with a higher  $K_m$  is being unmasked.

Carbon monoxide (CO) is a competitive inhibitor of cytochrome oxidase; we expect that  $Q =$

$$Q_{\text{max}} \cdot K / ([\text{CO}] / [\text{O}_2] + K),$$

where  $K$  is the ratio of

the affinities of the oxidase for  $\text{O}_2$  and CO respectively. Starting with an  $\text{O}_2/\text{CO}$  mixture,  $Q$  should decrease as  $[\text{O}_2]$  decreases, since  $[\text{CO}]$  does not change;  $[\text{CO}]/[\text{O}_2]$  is calculated from the measured  $[\text{O}_2]$  and the initial  $[\text{CO}]$ . As seen in Figure 3, the isolated gastric cells (solid points) are best fit by  $30 < K < 70$ ,

Figure 3 Effect of CO on  $Q$

while yeast cells (solid '+'s) have  $5 < K < 10$  appropriate to cytochrome oxidase. Strong light, which photodissociates the cytochrome oxidase-CO complex, increases the apparent  $K$  of gastric cells (open circles) at high  $[\text{CO}]/[\text{O}_2]$ , as it does with yeast (not shown). The " $K_m$ " with light decreases from  $7.73 \pm 0.82$  to  $2.62 \pm 0.42 \mu\text{M}$  ( $N=22$ ), but not to the CO-free level of  $1.42 \pm 0.16 \mu\text{M}$  ( $N=30$ ).

The cells have a respiration which is in-

sensitive to  $\text{N}_3^-$ ,  $\text{CN}^-$  and CO which is capable of 60 to 80% of control  $Q$ . This alternate oxidase may have a higher  $K_m$  for  $\text{O}_2$  than cytochrome oxidase, and its inhibition by CO is photoreversible. The cells also possess a conventional (sensitive) cytochrome oxidase, as shown by the inhibition of 20 to 40% of respiration at very low inhibitor concentrations. These findings are consistent with the spectrophotometric studies, and may indicate that gastric acid secretion is driven by a cytochrome system using the insensitive oxidase.
